# 1 Executive Summary

**Prism** is a full-stack developer tool designed to visualize the internal mechanics of **Retrieval-Augmented Generation (RAG)** pipelines. While most RAG tools act as "black boxes," Prism exposes the hidden data transformations—tokenization, chunking, vector embedding, and similarity search—allowing engineers to optimize their retrieval strategies before deployment.

## 2 System Architecture

The application follows a decoupled **Client-Server architecture**, separating the interactive UI from the heavy computational logic.

- **Frontend (Client):** Built with **React (Vite)** and **Tailwind CSS**. It handles state management, real-time rendering of chunks, and data visualization (using Recharts).
- **Backend (Server):** Built with **Python (FastAPI)**. It acts as the computational engine, handling natural language processing (NLP), mathematical calculations, and tokenization.

## 3 Core Features & Technical Logic

### 3.1 Recursive Text Chunking

**The Problem:** LLMs have context windows. Sending a 100-page PDF at once crashes the model or costs a fortune. We must break text into smaller "chunks."

**The Logic:** Prism uses LangChain's `RecursiveCharacterTextSplitter`. Unlike simple splitters that chop text at fixed indices (e.g., every 500 chars), this algorithm recursively tries to split text by a hierarchy of separators (`\n\n`, `\n`, `" "`, `"'"`) to keep paragraphs and sentences intact.

### 3.2 Overlap Calculation (Sliding Window)

**The Problem:** If a sentence is cut in half between Chunk A and Chunk B, the semantic meaning is lost ("Context Fragmentation").

**The Solution:** We create a "Sliding Window" overlap.

**The Algorithm:**

1. Take the *last*  $N$  characters of Chunk  $i$ .
2. Take the *first*  $N$  characters of Chunk  $i + 1$ .
3. Identify the exact intersection string.
4. The Frontend renders this intersection in **Yellow** to visually confirm that context is preserved across boundaries.

### 3.3 Search Simulation (TF-IDF & Cosine Similarity)

**The Feature:** Users can type a query (e.g., *"How do vectors work?"*) and see which chunk matches. **The Math:** Instead of calling an expensive external API (like OpenAI Embeddings), Prism simulates retrieval using **TF-IDF** and **Vector Space Models**.

### 3.3.1 1. The Vectorizer (TF-IDF)

We convert raw text into a numerical vector. The weight  $w$  of a term  $t$  in a document  $d$  is calculated as:

$$w_{t,d} = \text{tf}_{t,d} \times \text{idf}_t \quad (1)$$

Where:

- **TF (Term Frequency):** How often the word appears in the chunk.
- **IDF (Inverse Document Frequency):** Measures how "unique" a word is across all chunks.

$$\text{idf}_t = \log \left( \frac{N}{\text{df}_t} \right) \quad (2)$$

(Where  $N$  is total chunks, and  $\text{df}_t$  is number of chunks containing term  $t$ ).

### 3.3.2 2. The Similarity Metric (Cosine Similarity)

Once we have vectors for the Query ( $A$ ) and the Chunk ( $B$ ), we calculate how similar they are by measuring the cosine of the angle between them:

$$\text{similarity} = \cos(\theta) = \frac{A \cdot B}{\|A\| \|B\|} = \frac{\sum_{i=1}^n A_i B_i}{\sqrt{\sum_{i=1}^n A_i^2} \sqrt{\sum_{i=1}^n B_i^2}} \quad (3)$$

- **Result = 1.0:** The vectors are identical (Perfect Match).
- **Result = 0.0:** The vectors are orthogonal (No shared meaning).

## 3.4 Semantic Map (Dimensionality Reduction)

**The Feature:** A 2D Scatter Plot showing the "distance" between chunks. **The Logic:** TF-IDF vectors are **High-Dimensional** (often 10,000+ dimensions). We use **PCA (Principal Component Analysis)** to squash them into  $(x, y)$  coordinates.

1. **Covariance Matrix:** We calculate how every variable relates to every other variable.
2. **Eigen Decomposition:** We compute the principal directions (Eigenvectors) in which the data varies the most.
3. **Projection:** We project the data onto the top 2 Principal Components.

$$T = X \times W_L \quad (4)$$

(Where  $X$  is the original data and  $W_L$  is the matrix of top 2 eigenvectors).

## 3.5 Token "X-Ray" (Byte Pair Encoding)

**The Feature:** The "Matrix View" ribbon that breaks words into colored blocks. **The Logic:** LLMs do not see words; they see "Tokens." Prism uses `tiktoken` (OpenAI's tokenizer) which uses **BPE (Byte Pair Encoding)**.

- Common words (e.g., "apple") are 1 token.
- Complex words (e.g., "Unstoppable") are split into sub-words: `Un`, `stop`, `able`.

## 4 Frontend Visualization Strategy

- **Recharts:** Used for the Semantic Map (ScatterChart) and Confidence Monitor (Bar-Chart). The data is normalized in the backend before being sent to the frontend to ensure high rendering performance.
- **State Management:** React `useState` handles the complex dependency graph (e.g., changing `chunk_size` triggers a re-fetch, which recalculates `chunks`, which triggers a PCA re-calculation, which updates the `ScatterChart`).

## 5 Conclusion

Prism is not just a visualizer; it is a **mathematical proof of concept** for RAG. By exposing the vectors, tokens, and similarity scores, it transforms abstract AI concepts into concrete, debuggable engineering data.
